The AD505 achieves a minimum sleve ltage drift, are 100% tested. of 120V/µsec, provides an adjustable unity gain bandwidth product of 4MHz to 10MHz, and settles to 0.1% in 800nsec. maintains low bias currents 3 max In addition to its superior dynamic characteristics, the AD505 Vos drift of 15µV/°C max. and low maintains high gain, maximum offset voltage drift of $15\mu V/^{\circ}C$, 4. Ease of use and predictability of operation make the maximum bias currents of 25nA and high output swing. AD505 an all-purpose amplifier that is free of the The circuit has a stable 6dB/octave rolloff for closed loop problems found in most high frequency amplifier

operation. It is also capable of being externally adjusted for up to 35dB of additional closed loop gain at high frequencies, without causing the small signal or large signal bandwidth to decrease, and without increasing settling times.

The AD505 is designed for high speed inverting applications by using a feed-forward technique. It can drive capacitive loads in excess of 1000pF and is short circuit protected.

The AD505 provides performance superior to most high speed IC op amps and comparable to modular versions. Because of its monolithic construction, however, its cost is significantly below that of modules, and becomes even lower in large quantities.

All the circuits are supplied in the TO-100 package. The AD505J and AD505K are specified for 0° C to $+70^{\circ}$ C temperature range operation; the AD505S for operation from -55° C to $+100^{\circ}$ C.

SLEW RATE AND SETTLING TIME

Both slew rate and settling time are measures of an amplifier's speed of response to an input. Slew rate is an inherent characteristic of the amplifier and, thus, is generally less subject to misinterpretation than is settling time, which is often more dependent upon the test circuit than the amplifier's ability to perform.

Slew rate defines the maximum rate of change of output voltage for a large input step change and can be related to the full power response (f_p) by the relationship

$S = 2\pi f_p E_o$

 \ldots where E_0 is the peak output voltage.

(continued from page 1)

Settling time is defined as the time elapsed from the application of a fast step input to the time when the amplifier output has entered and remained within a specified error band that is symmetrical about the final value. Settling time, therefore, is comprised of an initial propagation delay, an additional time for the amplifier to slew to the vicinity of some value of output voltage, and a time period to recover from overload and settle within the given error band (see Figure 1).

ADI tests for slew rate and settling time in a unity gain configuration (RS = $R_f = 10k\Omega$), no capacitive load, and a -10 volt to a +10 volt output swing.

Figure 1. Settling Time of the AD505.

The full power response of the AD505 is displayed in Figure 2 for supply voltages of $\pm 15V$ and $\pm 10V$. Note that at $V_S = \pm 15V$ the full power response is greater than 2MHz and that it decreases as the supply voltages are lowered.

Figure 2. Full Power Response of the AD505.

APPLICATIONS CONSIDERATIONS

The AD505 combines excellent DC characteristics and dynamic performance with ease of application. Because it is a wideband, fast settling amplifier, certain practical stabilization and interconnection techniques are suggested to insure proper operation and minimize user experimentation. The feed-forward operation of the AD505 is shown in the block diagram in Figure 3. The DC signal is via the input differential current amplifier, followed by a gain stage. An external 390pF capacitor connected between pins 1 and 9 makes this gain stage an integrator and optimizes settling time. A 4700pF capacitor in series with a 100 Ω resistor is connected between pins 9 and 5 (V–) to provide a lag which insures that this portion of the amplifier rolls off to below unity gain above the frequency at which the fast DC amplifier starts its rolloff. The AC signal is fed forward by an external 0.02 μ F capacitor connected between pin 4 and pin 10 into the other differential input of the fast DC amplifier.

To help the user achieve best results with the AD505, here are a few reminders

- (1) Power supply bypasses should be provided as close to the amplifier as possible to eliminate ringing due to the inductance of power supply leads. A tantalum 10μ F capacitor in parallel with a ceramic 0.01μ F capacitor is sufficient for this purpose (see Figure 4).
- (2) All ground connections should be made at a single ground point.
- (3) Keep leads short to eliminate stray impedance effects.

Figure 4 shows an optimum wiring diagram of the AD505.

Figure 4. Wiring Diagram of the AD505.

GENERAL PURPOSE WIDEBAND COMPENSATION An approximate high frequency equivalent circuit of the AD505 is shown in Figure 5. The unity gain open loop gain bandwidth product can be adjusted over the range of 4MHz to 10MHz by selecting resistor (R_{BW}) which is connected between pin 4 and pin 3. The lowest gain bandwidth product is a result of an open circuit ($R_{BW} = \infty$) between pins 3 and 4, while the maximum is achieved by a short circuit $(R_{BW} = 0)$. Figure 6 displays the open loop frequency and phase response of the AD505. Note that as RBW decreases the open loop gain increases, and that the amplifier is stable as long as the loop unity gain crossover is below 10MHz. In the $R_{BW} = \infty$ condition, the leading phase shift above 200kHz is a result of stray capacitance across the 20k Ω input resistor, and can be used by the designer to increase network stability.

Rin

The input impedance at high frequencies can be represented by, in effect, a 350Ω resistor to common (the "Miller" impedance of a 1.5pF capacitor*). This low impedance effectively permits the amplifier to be stable (for large enough values of Rf) even at low values of signal gain. For example, with $R_{BW} = 0$, a stable gain of 10 (20dB) can be obtained using $R_S = 5k\Omega$ and $R_f = 50k\Omega$, since the input impedance of 500 Ω dominates the 5k Ω source resistor. Similarly, a gain of 50.....without any reduction in bandwidth.....can be obtained using a $1k\Omega$:50k Ω ratio.

*
$$Z_{in} \approx \frac{X_c(\omega)}{G(\omega)} = \frac{1}{2\pi \cdot f \cdot C \cdot G(\omega)} = 350\Omega \text{ at } f = 1 \text{ MHz},$$

where $G(\omega) =$ open loop gain as a function of frequency and $X_c(\omega)$ = reactive capacitance of capacitor.

Note: At high frequencies, Zin is approximately constant since f and $G(\omega)$ are inverse functions of frequency.

In order to provide application flexibility and low cost, the AD505 is externally compensated with several capacitors.

INPUT CHARACTERISTICS

In addition to its superior dynamic characteristics, the AD505 maintains low bias currents of 25nA max and a low Vos drift of $15\mu V/^{\circ}C$ max.

Figure 9 displays the input bias current vs. temperature characteristic of the AD505. Note that the bias current at room temperature is 15nA and increases to less than 25nA at -55°C.

Figure 9. Input Bias Current vs. Temperature.

Figure 10 displays the offset voltage drift characteristic of the AD505. Note that average temperature coefficient of the offset voltage is approximately $2.5\mu V/^{\circ}C$ for higher temperatures and $5.0\mu V/^{\circ}C$ for low temperatures.

Fast Output Buffer for Digital/Current Converter In this configuration, the converter and amplifier settle to within 0.1% (1 LSB) in 3μ s, and to within ½ LSB in 5μ s, typically. With the component values indicated, the AD505 can feed load impedance of $5k\Omega$ in parallel with 500pF. Interwiring capacitance between the converter output and the amplifier input, plus the converter's output capacitance, should be held to within 10pF if possible. When applied with the *bipolar* version of MDA-10Z, the built-in feedback resistor for $\pm 10V$ output is $10k\Omega$. The $20k\Omega$ R_{BW} shunt should be replaced by about $5k\Omega$.

Although the MDA-10Z is indicated in this example, the AD505 may be used to unload converters having output impedance values other than the MDA-10Z's $1.5k\Omega$. For example, when used with a 10-bit converter assembled from μ DAC switches and resistor networks, the external R_{BW} shunt may be omitted and a 7.5k Ω load connected from the summing point to ground.
